Monetary Policy and the Financing of Firms*

Fiorella De Fiore† Pedro Teles‡ and Oreste Tristani†

September, 2010

Abstract

How should monetary policy respond to changes in financial conditions? In this paper we consider a simple model where firms are subject to idiosyncratic shocks which may force them to default on their debt. Firms’ assets and liabilities are denominated in nominal terms and predetermined when shocks occur. Monetary policy can therefore affect the real value of funds used to finance production. Furthermore, policy affects the loan and deposit rates. In our model, allowing for short-term inflation volatility in response to exogenous shocks can be optimal; the optimal response to adverse financial shocks is to lower interest rates, if not at the zero bound, and to engineer a short period of controlled inflation; the Taylor rule may implement allocations that have opposite cyclical properties to the optimal ones.

Keywords: Financial stability; debt deflation; bankruptcy costs; price level volatility; optimal monetary policy; stabilization policy.

1 Introduction

During financial crises, credit conditions tend to worsen for all agents in the economy. In the press, there are frequent calls for a looser monetary policy stance, on the grounds that low nominal interest rates reduce the costs of external finance, thus countering the effects of the tightening of credit standards. Arguments tracing back to Fisher (1933) can also be used to call for some degree of inflation during financial crises, so as to avoid an excessive increase in firms’ leverage through a devaluation of their nominal liabilities.

It is less clear, however, whether these arguments would withstand a more formal analysis. In this paper, we present a model that can be used to evaluate them. Our set-up has three main features. First, firms’ internal and external funds are imperfect substitutes. This is due to the presence of information asymmetries between firms and banks regarding firms’ productivity, and to the fact that monitoring is a costly activity for banks. Second, firms’ internal and external funds are nominal assets. Third, those funds, both internal and external, as well as the interest rate on bank loans, are predetermined when aggregate shocks occur. The last two features, combined, distinguish our analysis from previous literature, in particular, Bernanke, Gertler and Gilchrist (1999) and Carlstrom and Fuerst (2001), and allow us to address issues related to the conduct of monetary policy when debt deflation or debt overhang may be major policy concerns.

More specifically, we address the following questions: How should monetary policy respond to financial shocks? How should it respond to other shocks, when financial conditions affect macroeconomic outcomes? Should monetary policy engineer inflation during recessions, in order to reduce real debt liabilities? How relevant is the zero bound on the nominal interest rate?

We find that, for the Ramsey planner, allowing for short-term inflation volatility in response to exogenous shocks can be optimal. In response to technology shocks, for example, the price level should move to adjust the real value of total funds. If the shock is negative, the price level increases on impact to lower real funds as well as the real wage. Subsequently, the price level falls in order to increase the real wage at the same pace as productivity, in the convergence back to the steady state. Along the adjustment path, deposit and loan rates, spreads, financial markups, leverage, and bankruptcy rates remain stable. Therefore, under the optimal policy,
and if technology shocks were the only shocks hitting the economy, bankruptcies would be acyclical.

The optimal response to a financial shock that reduces firms’ internal funds, increasing firms’ leverage, also involves an increase in the price level on impact. Because of the predetermination of funds, the shock only increases leverage with a delay. On impact it is optimal to generate inflation in order to reduce the real value of total funds, lowering production, and increasing mark ups. Profits are, therefore, higher, and there is a faster accumulation of internal funds. Firms can de-leverage more quickly.

In the baseline version of our model, i.e. the one without government consumption, the optimal deposit rate is zero, corresponding to the Friedman rule. Because assets are nominal and predetermined, a set path for the nominal interest rate does not pin down equilibrium allocations. Policy can additionally affect allocations through ex-post volatility of the price level.

To analyze the optimal interest rate reaction to shocks, we introduce government consumption as an exogenous share of production. This assumption generates a rationale for proportionate taxation. The nominal interest rate acts as a tax on consumption and therefore the optimal steady-state interest rate becomes positive – the Friedman rule is no longer optimal.

When the optimal average interest rate is away from the lower bound, it may be optimal for the interest rate to respond to shocks. This is indeed the case for financial shocks, but not for technology shocks. In the second case, it is optimal to keep rates constant even if they could be lowered. For financial shocks, the flexibility of moving the nominal interest rate downwards allows policy to speed up the adjustment process. Moreover, the effect of these shocks on output can be considerably mitigated. For instance, a shock that reduces the availability of internal funds is persistently contractionary when the short term nominal rate is kept fixed at zero, while it is less contractionary and has very short-lived effects on output when the average interest rate is away from the lower bound and the short term nominal rate is reduced.

In order to provide the intuition for the policy response to technology and financial shocks, it is useful to start from the benchmark of an economy without any distortions. In that economy the marginal rate of substitution is equal to the marginal rate of transformation. In our model, this is not the case. Asymmetric information and the scarcity of internal funds open a wedge between those two marginal rates, because more resources have to be used to produce goods.
That wedge is also affected by a nonzero policy rate, because a higher policy rate translates into higher deposit and loan rates. Movements in the policy rate can, at least partially, compensate for movements in the distortion created by the scarcity of internal funds. This is useful in response to financial shocks, but unnecessary in response to technology shocks.

In response to technology shocks, it is optimal to keep the wedge constant. This result is reminiscent of those on uniform taxation in the second best public finance literature. In that literature, even if taxes on average must be positive, for standard preferences and technologies, it is optimal to keep tax rates constant in response to shocks. Similar results are also obtained in models with sticky prices in second best contexts (see, for example, Adão, Correia and Teles, 2003). The wedge can be kept constant through appropriate movements in the price level. The real value of funds used for production can adjust, while financial conditions and labor remain unchanged. Since the distortion associated with scarce internal funds is constant, the nominal interest rate does not have to move.

Instead in response to financial shocks, the distortion created by the scarcity of internal funds moves. In particular when there is a negative financial shock, credit conditions worsen, and that distortion is higher. In this case it is optimal to move the nominal interest rate to partially undo the effects of that distortion and reduce the fluctuations in the wedge between the marginal rates of substitution and transformation. It is not optimal (nor feasible) to fully stabilize the wedge.

Compared to the optimal Ramsey plan, a policy response according to a simple Taylor-type rule can be costly, in the sense of inducing more persistent deviations in real variables from their optimal values and higher bankruptcy rates. In response to technology shocks, bankruptcies become countercyclical under the simple rule. In response to a financial shock that reduces internal funds, there is deflation initially, which increases the real value of total funds and leads to a much larger increase in leverage. The reduction in output is smaller than under the optimal policy and markups decrease, inducing higher bankruptcy rates.

In order to understand the mechanisms responsible for these results, we analyze a simplified model in which internal and external funds are perfect substitutes (i.e. monitoring costs are zero). We use this model to illustrate that the two assumptions of nominal denomination and predetermination of the funds used to finance production are sufficient conditions for changes in the price level to affect allocations. For this specific case, we show that, in response to a technology shock, optimal monetary policy aims at keeping the nominal wage constant. This
is achieved by inducing movements in the price level such that the real wage adjusts one-to-one to productivity. Because, under log-linear preferences, labor does not move, nominal predetermined funds are ex-post optimal.

This simplified case also highlights two advantages of the more general model with asymmetric information and monitoring costs. The first one is to allow for policy analysis in response to financial shocks. Financial shocks are indeed hard to think of in the simple environment in which internal and external funds are perfect substitutes. The second advantage of the model with asymmetric information and monitoring costs is to amplify the reaction of the economy to shocks, when monetary policy follows a simple rule.

This paper contributes to the literature that analyzes the effects of financial factors on the transmission of shocks. Financial factors play a role because of agency costs, as in Bernanke et al. (1999) and Carlstrom and Fuerst (1997, 1998, 2001). In Bernanke et al. (1999), agency costs are added to an otherwise standard New-Keynesian model, where monetary policy has real effects because of the presence of sticky prices. In Carlstrom and Fuerst (2001), prices are flexible but money affects real activity because of a cash-in-advance constraint on households’ purchases. In our model, prices are flexible but monetary policy has real effects because firms must use funds to pay wages and these funds are nominal and predetermined.

Our work is most closely related to a recent literature that analyzes optimal monetary policy in models with financial frictions (see e.g. Ravenna and Walsh (2006), Curdia and Woodford (2008), De Fiore and Tristani (2008), Carlstrom, Fuerst and Paustian (2009), and Faia (2009)).1 Ravenna and Walsh (2006) characterize optimal monetary policy when firms need to borrow to finance production, but there is no default risk and the cost of financing is the risk-free rate. Curdia and Woodford (2008) consider a model where financial frictions matter for the allocation of resources, because of the heterogeneity in households’ spending opportunities. In their setup, credit spreads arise because loans are costly to produce, but they are linked to macroeconomic conditions through a flexible reduced-form function. Instead, credit spreads emerge as the outcome of an optimal financial contract in De Fiore and Tristani (2008) and Faia (2009), while Carlstrom et al. (2009) model agency costs as a constraint on the firm’s hiring of labor. In all these papers, prices are assumed to be sticky. The main lesson from this literature is that, in the presence of financial frictions, both financial and non-financial shocks create a trade-off between inflation and output gap stabilization. Although perfect price

---

1See also Christiano, Motto and Rostagno (2003).
stability is in general not optimal; under reasonable calibrations, the welfare gains associated to price stability are much larger than those associated to mitigating the financial distortions.

The main distinguishing feature between these models and ours is the assumption that firms’ financing conditions are predetermined when aggregate shocks occur. In our model, the stock of internal funds, the amount of bank loans, and the interest rate on bank loans are not contingent on the realization of aggregate shocks. This enables us to study how changes in the inflation rate may have an impact on the dynamics of firms’ leverage. To study this particular channel of transmission of monetary policy, we abstract from other frictions, such as sticky prices.

Building upon the Bernanke et al. (1999) setup, Gilchrist and Leahy (2002) and Faia and Monacelli (2007) find that the presence of financial frictions does not provide a justification for reacting to asset prices directly. In reaction to a technology shock and to an expected technology shock, monetary policy should react to asset prices, but a policy that reacts strongly to inflation closely approximates the optimal policy. In our model, a policy that stabilizes prices performs slightly better than a simple Taylor rule that does not react aggressively to inflation. For the reasons discussed above, however, an aggressive policy response to inflation remains largely sub-optimal in our model.

The paper proceeds as follows. In section 2, we outline the environment and describe the equilibria. Then, we derive implementability conditions and we characterize optimal monetary policy. In section 3, we provide numerical results on the response of the economy to various shocks. We compare the case where optimal interest rate policy is the Friedman rule to the case where, because government consumption is assumed to be a fixed share of output, the optimal average interest rate is away from zero. We describe results both under the optimal monetary policy and a sub-optimal (Taylor) rule. In section 4, we analyze a simple model in which internal and external funds are perfect substitutes, and use it to provide some intuition on the results obtained for the general model. In section 5, we conclude.

2 Model

We consider a model where firms need internal and external funds to produce and they fail if they are not able to repay their debts. Both internal funds and firm debt are nominal assets.
There is a goods/labor market at the beginning of the period and an assets market at the end,\textsuperscript{2} where funds are decided for the following period. Funds are predetermined.

Production uses labor only with a linear technology. Aggregate productivity is stochastic. In addition, each firm faces an idiosyncratic shock whose realization is private information.

The households have preferences over consumption, labor and real money. For convenience we assume separability for the utility in real balances.\textsuperscript{3}

Banks are financial intermediaries. They are zero profit, zero risk operations. Banks take deposits from households and allocate them to entrepreneurs on the basis of a debt contract where the entrepreneurs repay their debts if production is sufficient and default otherwise, handing in total production to the banks, provided these pay the monitoring costs. Because there is aggregate uncertainty, we assume that the government can make lump sum transfers between the households and the banks that ensure that banks have zero profits in every state.\textsuperscript{4} This way the banks are able to pay a risk free rate on deposits.

Entrepreneurs need to borrow in advance to finance production. The payments on outstanding debt are not state dependent. Entrepreneurs are risk neutral, patient agents, that die with some probability. Their assets are seized at the time of death. In equilibrium they postpone consumption indefinitely. The tax on their assets at the time of death ensures that there is always a need for external funds.

The banks are owned, but not controlled,\textsuperscript{5} by the entrepreneurs. They behave as risk neutral agents, which is convenient since the financial contract is then between two risk neutral agents.

Monetary policy can affect the real value of total funds available for the production of firms, but it can also affect the real value of debt that needs to be repaid. Furthermore, monetary policy also affects the deposit and loan rates.

To be more specific about the timing of events, we decompose each period into three subperiods. In the first subperiod, aggregate shocks are revealed. Entrepreneurs hire labor, supplied by the households. They pay the wage bill using total funds, internal and external,

\begin{itemize}
  \item This is the timing of transactions in Svensson (1985).
  \item We also assume a negligible contribution of real balances to welfare. This does not mean that the economy is cashless since firms face a cash-in-advance constraint.
  \item We assume that the monitoring activities of banks can be observed, in order to keep the incentives to monitor unaffected by the insurance scheme. This amounts to assuming that bank supervision can be exercised at zero cost.
  \item Each entrepreneur owns an arbitrarily small share of each bank.
\end{itemize}
brought in from the previous period. They enter into production. In the second subperiod, the outcome of production - the idiosyncratic shock - is revealed to each entrepreneur. The entrepreneur either sells the produced goods, or declares bankruptcy in which case the bank appropriates production. Entrepreneurs make consumption decisions. A tax is levied on their consumption. Households also purchase consumption goods and pay lump-sum taxes. In the third subperiod, households make financial decisions, how to allocate their wealth to money, nominal state-contingent bonds, in zero net supply, and deposits. Entrepreneurs that did not declare bankruptcy pay debts to banks. Lump sum taxes/subsidies are levied on banks to ensure that profits are zero ex-post. Banks lend to entrepreneurs, entering nominal debt contracts that are noncontingent on aggregate shocks.

2.1 Households

The aggregate uncertainty in period \( t \geq 0 \) is described by the random variable \( s_t \in S_t \), where \( S_t \) is the set of possible events at \( t \), and the history of its realizations up to period \( t \) (state at \( t \)), \( (s_0, s_1, \ldots, s_t) \), is denoted by \( s^t \in S^t \). We assume that \( s_t \) has a discrete distribution. \( \Pr(s^{t+1} / s^t) \) is the probability of state \( s^{t+1} \), conditional on state \( s^t \). We index variables by the subscript \( t \) when they are a function of the state \( s^t \).

At the end of period \( t \) in the assets market, households decide on holdings of money \( M_t \) that they will be able to use at the beginning of period \( t + 1 \) in the goods market, and on one-period deposits denominated in units of currency \( D_t \) that will pay \( R_t D_t \) in the assets market in period \( t + 1 \). Deposits are riskless, in the sense that banks do not fail. The households also decide on a portfolio of nominal state-contingent bonds, \( B_{t,t+1} \), each paying a unit of currency in a particular state in period \( t + 1 \) and each costing \( Q_{t,t+1} \) units of money at \( t \).

The budget constraint at period \( t \) is

\[
M_t + \sum_{s^{t+1} / s^t} Q_{t,t+1} B_{t,t+1} + D_t \leq B_t + R_{t-1} D_{t-1} + M_{t-1} - P_t c_t + W_t n_t - T^h_t, \tag{1}
\]

where \( c_t \) is the amount of the final consumption good purchased, \( P_t \) is its price, \( n_t \) is hours worked, \( W_t \) is the nominal wage, and \( T^h_t \) are lump-sum nominal taxes collected by the government.

The household’s problem is to maximize utility, defined as

\[
E_0 \left\{ \sum_{0}^{\infty} \beta^t \left[ u(c_t, m_t) - \alpha n_t \right] \right\}, \tag{2}
\]
subject to (1) and a no-Ponzi games condition. Here \( u_c > 0, u_m \geq 0, u_{cc} < 0, u_{mm} < 0, \alpha > 0 \) and \( m_t \equiv M_{t-1}/P_t \) denotes real balances. Throughout we will assume that the utility function is separable in real money, \( m_t \), and that the contribution of money to welfare is negligible.

Optimality requires that the following conditions must hold:

\[
\frac{u_c(t)}{\alpha} = \frac{P_t}{W_t},
\]

\[
\frac{u_c(t)}{\beta \Pr(s^{t+1}/s^t) u_c(t+1)} = \frac{Q_{t,t+1}}{P_{t+1}},
\]

\[
\frac{u_c(t)}{P_t} = \frac{R_t E_t \beta u_c(t+1)}{P_{t+1}},
\]

\[
E_t \frac{u_m(t+1)}{P_{t+1}} = E_t \left( \frac{u_c(t+1)}{P_{t+1}} - R_t \right).
\]

\( u_c(t) \) is the marginal utility of consumption in state \( s^t \), and similarly for the other marginal utilities.

### 2.2 Production

The production sector is composed of a continuum of firms, indexed by \( i \in [0, 1] \). Each firm is endowed with a stochastic technology that transforms \( N_{i,t} \) units of labor into \( \omega_{i,t} A_t N_{i,t} \) units of output. The random variable \( \omega_{i,t} \) is i.i.d. across time and across firms, with distribution \( \Phi \), density \( \phi \), mean 1 and standard deviation \( \sigma_{\omega,t} \). In \( A_t \) is an AR (1) aggregate productivity shock. Aggregate shocks are observed at the beginning of the period, before production. The idiosyncratic shock \( \omega_{i,t} \) is observed by each firm after production, and is private information.\(^6\)

Its realization can be observed by the financial intermediary at the cost of a share \( \mu_t \) of the firm’s output.

The firms decide in the assets market at the end of period \( t - 1 \) the amount of internal funds to be available in period \( t \), \( Z_{i,t-1} \). Lending occurs through the financial intermediary. The existence of aggregate shocks occurring during the duration of the contract implies that the intermediary’s return from the lending activity is not safe, regardless of its ability to differentiate across the continuum of firms facing i.i.d. shocks. We assume the existence of a deposit insurance scheme that the government implements by completely taxing away the intermediary’s profits whenever the aggregate shock is relatively high, and by providing

---

\(^6\)The assumption that the idiosyncratic shocks are observed at the end of the period, after production, is the standard assumption in this literature (see Bernanke et al., 1999).
subsidies up to the point where profits are zero when the aggregate shock is relatively low. Such scheme is financed with lump-sum taxes and transfers to the household. It guarantees that the intermediary is always able to repay the safe return to the household, thus insuring households’ deposits from aggregate risk.

2.2.1 The financial contract

The firms must pay wages in the beginning of the period, before receiving the sales from production. They have to bring in nominal funds from the previous period in order to do so. Each firm is, thus, restricted to hire and pay wages according to

\[ W_{t}N_{i,t} \leq X_{i,t-1}, \]  

(7)

where \( X_{i,t-1} \) are total funds, internal plus external, decided at the assets market in period \( t-1 \), to be available in period \( t \). The firms have internal funds \( Z_{i,t-1} \) and borrow \( X_{i,t-1} - Z_{i,t-1} \), according to a loan contract.

At the beginning of period \( t \), firms observe the aggregate shocks and decide whether to produce, before observing the idiosyncratic shock. We impose conditions under which it is efficient to produce, and the optimal contract guarantees that the firm will produce (see footnote 7).

The loan contract stipulates a payment of \( R_{i,t-1}^{d} (X_{i,t-1} - Z_{i,t-1}) \), where \( R_{i,t-1}^{d} \) is not contingent on the state at \( t \), when the firm is able to meet those payments, i.e. when \( \omega_{i,t} \geq \overline{\omega}_{i,t} \), where \( \overline{\omega}_{i,t} \) is the minimum productivity level such that the firm is able to pay the fixed return to the bank, so that

\[ P_{t}A_{t}\overline{\omega}_{i,t}N_{i,t} = R_{i,t-1}^{d} (X_{i,t-1} - Z_{i,t-1}) . \]  

(8)

Otherwise the firm goes bankrupt, and hands out all the production \( P_{t}A_{t}\omega_{i,t}N_{i,t} \). In this case, a constant fraction \( \mu_{t} \) of the firm’s output is destroyed in monitoring, so that the bank gets \( (1 - \mu_{t}) P_{t}A_{t}\omega_{i,t}N_{i,t} \).

Define the average share of production accruing to the firms and to the bank, respectively, after the repayment of the debt, as

\[ f (\overline{\omega}_{i,t}) = \int_{\overline{\omega}_{i,t}}^{\infty} (\omega_{i,t} - \overline{\omega}_{i,t}) \Phi (d\omega) . \]  

(9)

and

\[ g (\overline{\omega}_{i,t}; \mu_{t}) = \int_{0}^{\overline{\omega}_{i,t}} (1 - \mu_{t}) \omega_{i,t} \Phi (d\omega) + \int_{\overline{\omega}_{i,t}}^{\infty} \overline{\omega}_{i,t} \Phi (d\omega) . \]  

(10)
Total output is split between the firm, the bank, and monitoring costs
\[ f(\overline{r}_{i,t}) + g(\overline{r}_{i,t}; \mu_t) = 1 - \mu_t G(\overline{r}_{i,t}), \]
where \( G(\overline{r}_{i,t}) = \int_0^{\overline{r}_{i,t}} \omega_t \Phi(d\omega) \). On average, \( \mu_t G(\overline{r}_{i,t}) \) of output is lost in monitoring.

The optimal contract is a vector \( \left( R^d_{i,t-1}, X_{i,t-1}, \overline{r}_{i,t}, N_{i,t} \right) \) that solves the following problem. Maximize the expected production accruing to firms, after repaying the debt,
\[
\max \ E_{t-1} [ f(\overline{r}_{i,t}) P_t A_t N_{i,t}] 
\]
subject to
\[
W_t N_{i,t} \leq X_{i,t-1} \quad (11)
\]
\[
E_{t-1} [ g(\overline{r}_{i,t}; \mu_t) P_t A_t N_{i,t}] \geq R^d_{i,t-1} (X_{i,t-1} - Z_{i,t-1}) \quad (12)
\]
\[
E_{t-1} [ f(\overline{r}_{i,t}) P_t A_t N_{i,t}] \geq R^d_{i,t-1} Z_{i,t-1} \quad (13)
\]
where \( g(\overline{r}_{i,t}; \mu_t) \) and \( f(\overline{r}_{i,t}) \) are given by (9) and (10), respectively, and \( \overline{r}_{i,t} \) is given by (8).

The informational structure in the economy corresponds to a costly state verification (CSV) problem. The optimal contract maximizes the entrepreneur’s expected return subject to the borrowing constraint for firms, (11), the financial intermediary receiving an amount not lower on average than the repayment requested by the household (the safe return on deposits), (12), and the entrepreneur being willing to sign the contract, (13).

The decisions on \( X_{i,t-1} \) and \( Z_{i,t-1} \) are made in period \( t - 1 \) at the assets market. We can replace \( N_{i,t} = \frac{X_{i,t-1}}{W_t} \) and divide the constraints by \( X_{i,t-1} \) to get
\[
\max \ E_{t-1} \left[ \frac{P_t A_t}{W_t} X_{i,t-1} f(\overline{r}_{i,t}) \right] \quad (14)
\]
subject to
\[
E_{t-1} \left[ \frac{P_t A_t}{W_t} g(\overline{r}_{i,t}; \mu_t) \right] \geq R^d_{i,t-1} \left( 1 - \frac{Z_{i,t-1}}{X_{i,t-1}} \right) \quad (15)
\]
\[
E_{t-1} \left[ \frac{P_t A_t}{W_t} f(\overline{r}_{i,t}) \right] \geq R^d_{i,t-1} \frac{Z_{i,t-1}}{X_{i,t-1}} \quad (16)
\]

The problem is written under the restriction that the firm will produce. This is constrained efficient (for both firm and bank), as long as \( [1 - \mu_t G(\overline{r}_{i})] P_t A_t N_{i,t} \geq X_{i,t-1} \). The firm can be induced to produce by an optimal contract stipulating that if it does not, the bank will appropriate all the funds. If it is optimal for the firm to produce, then the financial constraint (11) holds with equality, so that it is efficient that the firm produces provided \( \frac{P_t A_t}{W_t} \geq \frac{1}{1 - \mu_t G(\overline{r}_{i})} \). As long as the economy is sufficiently distorted (because the deposit rate and/or the credit spreads are high enough), and shocks are small, this condition will be satisfied (see condition (27), below).
where \( f(w_{i,t}) \) and \( g(w_{i,t}; \mu_t) \) are given by (9) and (10), respectively, and where \( \omega_{i,t} \), defined by (8), can be rewritten as
\[
\omega_{i,t} = \frac{R_{i,t-1}^l A_t W_t}{1 - \frac{Z_{i,t-1}^l}{X_{i,t-1}}}
\]

Given that \( Z_{i,t-1} \) is exogenous to this problem and is predetermined, we can multiply and divide the objective by \( Z_{i,t-1} \), so that the problem is written in terms of \( Z_{i,t-1} \), \( R_{i,t-1}^l \), and \( \omega_{i,t} \). The only firm specific variable would be \( Z_{i,t-1} \) in the objective, but this would be irrelevant for the maximization problem. Hence, the solution for \( Z_{i,t-1} \), \( R_{i,t-1}^l \), and \( \omega_{i,t} \) is the same across firms.

Define \( z_{t-1} = \frac{Z_{i,t-1}^l}{X_{i,t-1}} \) and \( v_t = \frac{P_t A_t}{W_t} \). We can then rewrite \( \omega_{i,t} \) as
\[
\omega_{i,t} = \omega_t = \frac{R_{i,t-1}^l (1 - z_{t-1})}{v_t}
\]

This condition, defining the bankruptcy threshold, together with the first-order conditions of the optimal contract problem, which can be written as
\[
E_{t-1} [v_t f(\omega_t)] = \frac{R_{i,t-1}^l}{1 - z_{t-1}} z_{t-1}
\]
and
\[
E_{t-1} [v_t g(\omega_t; \mu_t)] = R_{i,t-1}^l (1 - z_{t-1})
\]
characterize the optimal \( (R_{i,t-1}^l, z_{t-1}, \omega_t) \).

### 2.3 Entrepreneurs

The assumptions on the entrepreneurs are as in Bernanke et al. (1999). Entrepreneurs die with probability \( \gamma_t \). They have linear preferences over consumption with rate of time preference \( e \). We assume \( e \) sufficiently high so that the return on internal funds is always higher than the preference discount rate, \( \frac{1}{\beta} - 1 \). It follows that the entrepreneurs postpone consumption until the time of death. When entrepreneurs die, or go bankrupt, they are reborn, or restart, with \( \varepsilon \) funds, that can be made arbitrarily small, transferred to them from the government. For reasons that will become clear when we discuss optimal policy, we depart from Bernanke et al. in assuming that consumption of entrepreneurs is taxed at a constant rate.

The constant consumption tax rate does not affect marginal decisions. For the individual entrepreneur, one more unit of consumption at \( t \), means that there will be less \( 1 + \gamma_t \) units of real internal funds to be available for production at \( t + 1 \). These funds earn expected return
\[
\frac{1 + \gamma_t}{1 + \gamma_{t+1}}
\]
in units of consumption at \( t + 1 \). If

\[\text{This is shown in Appendix A.1}\]
\[ 1 < (1 + \tau_t) \beta_e E_t \frac{1 + r_t^e}{1 + \tau_t + 1}, \]
then it is better to postpone consumption. Tax rates do not affect the decision, as long as they are constant. Every entrepreneur postpones consumption to the time of death if

\[ \frac{1}{\beta^e} < 1 + r_t^e. \]

The aggregate accumulation of internal funds is given by

\[ Z_t = f(\bar{\omega}_t) P_t A_t N_t - (1 + \tau) C_t^e \quad (20) \]

where the aggregate expenditure on consumption, \((1 + \tau) C_t^e\), is equal to the funds of the entrepreneurs that die, so that,

\[ C_t^e = \frac{\gamma_t f(\bar{\omega}_t) P_t A_t N_t}{1 + \tau}. \quad (21) \]

The accumulation of funds can be written as

\[ Z_t = (1 - \gamma_t) f(\bar{\omega}_t) P_t A_t N_t = (1 - \gamma_t) f(\bar{\omega}_t) \frac{\nu_t}{z_{t-1}} Z_{t-1}. \quad (22) \]

Taxes do not affect the accumulation of funds.

In the steady state, real internal funds are constant, meaning that

\[ (1 - \gamma) (1 + r^e) = 1, \]

where \(1 + r^e = \frac{f(\bar{\omega})}{\Pi}\), where \(\Pi\) is steady state gross inflation. For the individual entrepreneur, the decision to postpone consumption requires

\[ \frac{1}{\beta^e} < 1 + r^e, \]

so that

\[ \frac{1}{\beta^e} < \frac{1}{1 - \gamma}, \]

which is not restrictive on the discount rate of entrepreneurs.

### 2.4 Government

The accumulation of liabilities by the government is governed by the period \(t\) constraint

\[ M_t^s + \sum_{s^{t+1}/s^t} Q_{t,t+1} B_{t,t+1}^s \geq B_t^s + M_{t-1}^s + g P_t A_t N_t \left[ 1 - \mu_t G(\bar{\omega}_t) \right] - T_t, \quad (23) \]
where $T_t = T_t^h + T_t^e + T_t^b$, $T_t^h$ are the net tax revenues from the entrepreneurs, $T_t^b$ are the taxes/subsidies on the profits/losses of banks, and $M_t^s$ and $B_{t+1}^s$ are the supply of money and state contingent assets, respectively. We assume that government consumption is a share $g$ of production net of the monitoring costs.

### 2.5 Equilibria

The equilibrium conditions are given by equations (3)-(6), (7) holding with equality, (17), (18), (19),

$$Z_{i,t} = z_t X_{i,t},$$

(24)

together with (22), the resource constraints

$$c_t = (1 - g) A_t N_t [1 - \mu_t G(\overline{\zeta}_t)],$$

(25)

and the remaining market clearing conditions

$$M_t + Z_t = M_t^s$$

$$B_t = B_t^s$$

$$D_t = X_t - Z_t,$$

$$\int N_{i,t} di = N_t = n_t$$

where $\int Z_{i,t} di = Z_t$, $\int X_{i,t} di = X_t$, and where $f(\overline{\zeta}_t)$ and $g(\overline{\zeta}_t; \mu_t)$ are given by (9) and (10), respectively, with $\overline{\zeta}_t$ replacing $\overline{\zeta}_{it}$.

Aggregating across firms and imposing market clearing, we can write conditions (7) and (24) as

$$\frac{Z_{t-1}}{P_t} = z_{t-1} \frac{A_t}{v_t} n_t,$$

and

$$z_t = \frac{Z_t}{X_t},$$

(26)

We can also use the definition of $v_t$ in equation (3), (18) and (19), and combine these last two equations, together with $f(\overline{\zeta}_t) = 1 - \mu_t G(\overline{\zeta}_t) - g(\overline{\zeta}_t; \mu_t)$, to obtain

$$E_{t-1} \left[ \frac{u_t(t)}{\alpha} \frac{A_t}{E_{t-1}} \left[ 1 - \mu_t G(\overline{\zeta}_t) - f(\overline{\zeta}_t) E_{t-1} [\mu_t \overline{\zeta}_t \phi(\overline{\zeta}_t)] \right] \right] = R_{t-1}^d, \; t \geq 1.$$  

(27)

The equilibrium conditions are summarized in Appendix A.2, where we also show that, given a set path for the price level, there is a unique equilibrium for all the other variables.
2.6 Optimal policy

We consider optimal Ramsey policy, with commitment. The assumption of commitment is relevant since the Ramsey policy is not time consistent. At any point in time, it would be possible to lower the price level to increase the real value of funds, and lower the distortion associated with the costly state verification (and limited internal funds). This would be optimal ex-post, but not necessarily ex-ante. At time zero, it would be optimal to do it, once and for all. We abstract from the optimal policy at time zero, in accordance with the timeless perspective in Woodford (2003).

The objective is to maximize the welfare of the households. We have allowed for a constant consumption tax on the entrepreneurs that acts as a lump-sum tax. We consider the limiting case where entrepreneurs are fully taxed. Entrepreneurial consumption is zero, their utility is zero, and therefore their weight in the welfare function does not matter.

An alternative approach would be to allow entrepreneurs to consume, and give them an arbitrary weight in the utility function. Because entrepreneurs must be risk neutral in order to write optimal debt contracts with the banks, and because households are risk averse, the planner would use policy to try to insure households against aggregate shocks. The planner would also use policy to redistribute resources between the households and the entrepreneurs, to a different extent depending on their relative weights. In particular, the average nominal interest rate, that is a tax on entrepreneurs because they need to use funds in advance of production, could be higher (or lower, depending on the weights) for this reason. If we thought of these entrepreneurs as actual agents with a clear empirical counterpart, we would have no choice but to include them in the social welfare function. But we don’t. Entrepreneurs in this context are a modelling device to introduce a financial friction associated with an external finance premium. In order to ignore them in terms of welfare, their consumption should also be set to zero.

We have assumed that government consumption is a share of production net of monitoring costs. This assumption has important implications for the optimal average nominal interest rate. Since a share of resources $g$ are wasted, it is optimal to distort production at a rate that is approximately equal to $g$. When $g = 0$, the Friedman rule is optimal in steady state, $R^d = 1$, as we show below, analytically. The Friedman rule is also optimal in response to shocks, in

\[ If \text{the level, and not the share, of government consumption was exogenous, the results would be as in the case of } g = 0. \]
the calibrated version we analyze below.\textsuperscript{10} Instead, when $g > 0$, as also shown below, it is optimal to distort the consumption-leisure margin, even if lump-sum taxes are available. Since the nominal interest rate acts as a consumption tax, it is optimal to set it higher than zero.\textsuperscript{11}

We compute the optimal allocations, as well as the prices and policies that support them. We abstract from the issue of how to implement the optimal allocation. It is well known that, in monetary economies, setting the path for the nominal interest rate does not uniquely pin down equilibrium price levels. Because, in the economies we study here, the funds are nominal and predetermined, the allocations are also not uniquely pinned down. If the path for the price level is set exogenously, then there is a unique equilibrium. One way to think of policy would be that the central bank picks the path of interest rates and the price level, in some, but not all, states. How the price level can be targeted with policy instruments, other than the short term nominal interest rate, is a question that is beyond the scope of this paper. Adão, Correia and Teles (2010) is one of the many papers where this question of implementation is discussed.

\textbf{2.6.1 Optimal steady-state policy}

In order to show that, when $g = 0$, the Friedman rule is optimal in the steady state, we first show that steady-state bankruptcy rates are independent of monetary policy.

The following steady state conditions determine $R^d_l$, $v$, $z$, $\overline{w}$, and $R^d_l$, for given gross inflation $\Pi$, which is determined by policy:

\begin{align*}
\frac{1}{\beta} &= \frac{R^d_l}{\Pi} \\
vr (\overline{w}) &= \frac{R^d_l}{1 - \mu \overline{w}} z \tag{28} \\
v (\overline{w}) &= R^d_l (1 - z) \tag{29} \\
\Pi &= (1 - \gamma) f (\overline{w}) \frac{v}{z} \tag{30} \\
\overline{w} &= R^d_l (1 - z) \frac{v}{z} \tag{31}
\end{align*}

The first condition is the Euler equation, (5), in the steady state. The second and third conditions are the steady state conditions of the contract, (18) and (19). The fourth condition

\textsuperscript{10}This is the case if shocks are small, but not necessarily otherwise.

\textsuperscript{11}This is not a justification for positive average nominal interest rates, but rather it is a device to allow for movements in the nominal interest rate. If there were consumption or labor income taxes, the Friedman rule would again be optimal.
is the condition for the accumulation of internal funds in the steady state, (22), meaning that the growth rate of internal funds has to be equal to inflation in order for real internal funds to remain constant. Finally, the last condition is the definition of the bankruptcy threshold, (17), in the steady state.

From these conditions, it is clear that higher average inflation in this economy is transmitted one-to-one to the deposit rate, and also to the lending rate. The mark up, \( v \), increases, also in the same proportion, because of the intratemporal distortion created by the higher opportunity cost of funds for the firms. Higher average inflation does not affect the conditions of the contract so that the bankruptcy rate and the leverage rate are unchanged. Average inflation is neutral as far as those financial variables are concerned.

Using conditions (28)-(31), we can write
\[
\frac{1 - \gamma}{\beta} = 1 - \frac{\mu \varphi (\varpi)}{1 - \Phi (\varpi)},
\]
and
\[
\frac{f (\varpi)}{g (\varpi)} = \frac{z}{1 - \mu \varphi (\varpi) / \Phi (\varpi)}
\]
that determine \( \varpi \) and \( z \), independently of average inflation, and
\[
\Pi = (1 - \gamma) f (\varpi) \frac{A_{uc}}{z}
\]
that determines \( c \), given \( \Pi \). In the log case, an increase in \( \Pi \) leaves \( \varpi \) and \( z \) unchanged and lowers consumption and labor in the same proportion.

The equilibrium restrictions in the steady state can be simplified to the implementability condition
\[
\frac{u_c A}{\alpha} = \frac{R^d}{1 - \mu G (\varpi) - f (\varpi) \frac{\mu \varphi (\varpi)}{1 - \Phi (\varpi)}},
\]
the condition that \( \varpi \) does not depend on policy, (33), and the resource constraint,
\[
(1 - g) AN [1 - \mu G (\varpi)] = c,
\]
together with the implicit restriction that the nominal interest rate cannot be negative, \( R^d \geq 1 \).

The objective is to maximize steady-state utility \( u (c) - \alpha n \), subject to those restrictions.

We consider first the case where \( g = 0 \). For an exogenous \( \varpi \), which by (33) is independent of policy, suppose we were to maximize utility, subject to the steady-state resource constraint (36) only. Then, optimality would require that
\[
\frac{u_c A}{\alpha} = \frac{1}{1 - \mu G (\varpi)}.
\]
From (35), this could only be satisfied if either $\mu = 0$ or $\omega = 0$, and $R^d = 1$. When credit frictions are present, and $f(\omega) \frac{\mu \phi(\omega)}{1 - \Phi(\omega)} \neq 0$, there is a reason to subsidize consumption, which in this economy can only be done by reducing the nominal interest rate. Since $R^d \geq 1$, it is optimal to set $R^d = 1$, as a corner solution. The Friedman rule is optimal.

How can we interpret the optimal subsidy? The subsidy is a second best response to the restriction on the accumulation of internal funds. If $z = 1$, there would be no need for external financing and

$$\omega = \frac{R^d (1 - z)}{v} = 0.$$  

Since

$$\frac{u_c A}{\alpha} = \frac{R^d}{1 - \mu G(\omega) - \mu f(\omega) \frac{\phi(\omega)}{1 - \Phi(\omega)}} = R^d,$$

then

$$R^d = R^l = 1$$

would be exactly optimal, and there would be no reason to subsidize. The scarcity of internal funds is a second best restriction that justifies the subsidy to production.

With $g$ sufficiently greater than zero it is optimal to tax on average. The same argument as above cannot go through. The optimal condition just using the resource constraint would require that

$$\frac{u_c A}{\alpha} = \frac{1}{(1 - g) [1 - \mu G(\omega)]},$$

In spite of the reason to subsidize, due to $f(\omega) \frac{\mu \phi(\omega)}{1 - \Phi(\omega)}$, if $g$ is high enough, it is optimal to tax. Then, as we show in the simulations below, it will be optimal to tax at different rates, in response to financial shocks.

2.6.2 Optimal cyclic policy

When $g = 0$, in the calibrated version we analyze below, the Friedman rule is optimal also in response to shocks. From condition (27), at the lower bound, we obtain

$$E_{t-1} \left[ \frac{u_c(t) A_t}{\alpha} \left[ 1 - \mu_t G(\omega_t) - f(\omega_t) \frac{E_{t-1} \left[ \mu_t \omega_t \phi(\omega_t) \right]}{E_{t-1} \left[ 1 - \Phi(\omega_t) \right]} \right] \right] = 1.$$  

This condition provides some intuition on what is at stake for optimal policy. $\frac{u_c(t) A_t}{\alpha}$ is the wedge between the marginal rate of substitution and the marginal rate of transformation if the financial technology is not taken into account. The term

$$\frac{1}{1 - \mu_t G(\omega_t) - f(\omega_t) \frac{E_{t-1} \left[ \mu_t \omega_t \phi(\omega_t) \right]}{E_{t-1} \left[ 1 - \Phi(\omega_t) \right]}},$$

is the
financial markup present in models with costly state verification, and limited internal funds. If internal funds were not limited, there would be no markup. The wedge has to be equal to the financial markup, on average, but not always in response to shocks.

One of the frictions in this economy is the predetermination of funds, which is a nominal rigidity. If this was the single friction, meaning that \( \mu_t = 0 \), and the nominal interest rate was zero, then condition (38) would be written as

\[
E_{t-1} \left[ \frac{u_c(t)A_t}{\alpha} \right] = 1. \tag{39}
\]

The reason why this equilibrium condition is in expectation is precisely because of the predetermination of nominal assets. In this case the goal of policy would be to move the price level so that the markup \( \frac{u_c(t)A_t}{\alpha} \) would be exactly equal to one. Policy would be able to eliminate the single friction in the economy, neutralizing the nominal rigidity.\(^{12}\)

The nominal rigidity associated with the predetermination of nominal assets can be eliminated, as well as the distortion associated with a positive nominal interest rate due to the restriction that wages must be paid before firms receive production. The financial friction associated with the costly state verification cannot be fully eliminated. This economy is in a second or third best, where all these frictions interact.\(^{13}\) The financial distortion would justify subsidizing production which, given the zero bound on interest rates, is not possible. In response to shocks, specifically to shocks to technology, it may be optimal to neutralize the friction due to the predetermination of nominal assets, and to stabilize bankruptcy rates. In response to financial shocks, that is no longer the case.

As the numerical results will show, for logarithmic preferences, the optimal policy in response to technology shocks is to fully stabilize the financial markup, therefore keeping bankruptcy rates constant, and setting the wedge equal to the constant financial markup. Given that utility is logarithmic, consumption is proportional to the technology shock, which implies that labor does not move. From (11), we have that \( X_{t-1} = \frac{P_t A_t}{v_t} N_t \). Since \( N_t = N \), \( v_t = v \), and \( X_{t-1} \) does not vary with shocks in \( t \), it must be that the price level is inversely proportional to the technology shock. Since nominal funds are predetermined and labor does not move, the optimal policy is to keep the nominal wage constant and adjust the price level to the movements in the real wage.

\(^{12}\)We expand on this in Section 4.

\(^{13}\)The restriction that government spending is a share of production can also be seen as another distortion.
When the share of government spending is positive, \( g > 0 \), it is no longer the case that the Friedman rule is optimal. On average it is optimal to set a positive nominal interest rate, \( R^d_t > 0 \). The relevant equilibrium condition is no longer (38), but (27), where the wedge between the marginal rate of substitution and the marginal rate of transformation (without an external finance premium), \( \frac{u_c(t)A_t}{\alpha} \), is on average not only affected by the financial mark up but also by the nominal interest rate. On impact the nominal interest rate cannot be moved, but it can be in the future. The deterministic path of the equilibrium variables will then be described by

\[
\frac{u_c(t)A_t}{\alpha} = \frac{R^d_{t-1}}{1 - \mu_t G(\bar{z}_t) - f(\bar{z}_t) \frac{\mu_t\bar{z}_t\phi(\bar{z}_t)}{1-\Phi(\bar{z}_t)}}. \tag{40}
\]

The policy rate can be moved to offset the movements in the financial markup, stabilizing the wedge \( \frac{u_c(t)A_t}{\alpha} \).

In response to a technology shock, price level policy on impact can fully stabilize the financial mark up, so that there is no reason for the nominal interest rate to move. The optimal policy stabilizes the financial mark up and the wedge \( \frac{u_c(t)A_t}{\alpha} \), without movements in the nominal interest rate. Instead, in response to a financial shock, that has a direct effect on the financial mark up, it is not optimal (nor feasible) to stabilize that markup. The nominal interest rate adjusts to smooth the effects of the financial markup on the wedge \( \frac{u_c(t)A_t}{\alpha} \).

3 Numerical results

The model calibration is very standard. We assume utility to be logarithmic in consumption and linear in leisure. Following Carlstrom and Fuerst (1997), we calibrate the volatility of idiosyncratic productivity shocks and the steady state death probability \( \gamma \), so as to generate an annual steady state credit spread of approximately 2\% and a quarterly bankruptcy rate of approximately 1\%.\(^{14}\) The monitoring cost parameter \( \mu \) is set at 0.15 following Levin et al. (2004).

In the rest of this section, we always focus on adverse shocks, i.e. shocks which tend to generate a fall in output. Impulse responses under optimal policy refer to an equilibrium in which policy is described by the first order conditions of a Ramsey planner deciding allocations for all times \( t \geq 1 \), but ignoring the special nature of the initial period \( t = 0 \). Responses under

\(^{14}\)The exact values are 1.8\% for the annual spread and 1.1\% for the bankruptcy rate.
A Taylor rule refers to an equilibrium in which policy is set according to the following simple interest rate rule:

$$\bar{r}_t^d = 1.5 \cdot \hat{\pi}_t$$

(41)

where $$r_t^d \equiv \ln R_t^d$$, $$\pi_t \equiv \ln (P_t/P_{t-1})$$ and hats denote logarithmic deviations from the non-stochastic steady state.

In all cases, we only study the log-linear dynamics of the model.

### 3.1 Impulse responses under optimal policy

Optimal policy in the calibrated version of the model entails setting the nominal interest rate permanently to zero, as long as $$g = 0$$. This restriction is imposed when computing impulse responses.

#### 3.1.1 Technology shocks

Figure 1 shows the impulse response of selected macroeconomic variables to a negative, 1% technology shock under optimal policy, for $$g = 0$$. The variables are the technology process $$a_t \equiv \ln A_t$$, output $$y_t \equiv \ln (A_tN_t)$$, real internal funds $$z_t \equiv \ln (Z_{t-1}/P_t)$$, and inflation $$\pi_t$$. Bankruptcy rates, markups, spreads, and leverage are not represented because there is no effect of the shock on those under the optimal policy.

It is important to recall that the model includes many features which could potentially lead to equilibrium allocations that are far from the first best: asymmetric information and monitoring costs; the predetermination of financial decisions; and the nominal denomination of debt contracts. At the same time, the presence of nominal predetermined contracts implies that monetary policy is capable of affecting allocations by choosing appropriate sequences of prices.

Figure 1 illustrates that optimal policy is able to replicate the first-best response of consumption and labor allocations to a technology shock.\(^{15}\) In response to the negative technology shock, since nominal internal and external funds are predetermined, optimal policy generates inflation for 1 period. As a result, the real value of total funds needed to finance production falls exactly by the amount necessary to generate the correct reduction in output.

In subsequent periods, the real value of total funds is slowly increased through a mild reduction in the price level. Along the adjustment path, leverage remains constant and firms

\(^{15}\)The allocations are distorted, but the responses are as in the first best.
make no losses. Consumption moves one-to-one with technology, while hours worked remain constant. With constant labor and an equilibrium nominal wage that stays constant, the restriction that funds are predetermined is not relevant. The price level adjusts so that the real wage is always equal to productivity. Since total funds are always at the desired level, the accumulation equation for nominal funds never kicks in.
Figure 1: Impulse responses to a negative technology shock under optimal policy

Note: Logarithmic deviations from the non-stochastic steady state. Correlation of the shock: 0.9.

The impulse responses in Figure 1 would obviously be symmetric after a positive technology shock. Hence, perfect inflation stabilization – i.e. an equilibrium in which inflation is kept perfectly constant at all points in time – is not optimal (we show below that this is the case for all shocks, not just technology shocks). Allowing for short-term inflation volatility is useful to help firms adjust their funds, both internal and external, to their production needs. In the case of technology shocks, this policy also prevents any undesirable fluctuations in the economy’s bankruptcy rate, financial markup, or the markup resulting from the predetermination of assets.

This result, that inflation stabilization is not optimal, is robust to a number of perturbations of the model. It also holds if there are reasons not to keep the nominal interest rate at zero. And it holds in a model where internal and external funds are perfect substitutes.
3.1.2 Financial shocks

We can analyze the impulse responses to three types of financial shocks. The first is an increase in $\gamma_t$, namely a shock which generates an exogenous reduction in the level of internal funds. The second one is a shock to the standard deviation of idiosyncratic technology shocks, $\sigma_{\omega_i,t}$, which amounts to an increase in the uncertainty of the economic environment. The third shock is an increase in the monitoring cost parameter $\mu_t$. In the text, we focus on the first shock. The other two shocks are analyzed in Appendix 3.

Contrary to the case of Figure 1, bankruptcy rates, markups, spreads, and leverage are not constant after financial shocks. In all these cases, therefore, we also report impulse responses of: the log of internal to total funds, $z_t \equiv \ln \left( \frac{Z_t}{X_t} \right)$; log-consumption, $c_t$; the share of firms that go bankrupt, $\Phi_t$; the log-markup, $v_t$; the spread between the lending and the deposit rate, $\Delta_t \equiv \ln \left( \frac{R^l_t}{R^d_t} \right)$.

The impulse responses to $\gamma_t$ in Figure 2 are interesting because they generate at the same time a reduction in output and an increase in leverage. Leverage can be defined as the ratio of external to internal funds used in production, i.e. as $1/z_t - 1$ and it is therefore negatively related to $z_t$. To highlight the different persistence of the effects of the shock, depending on the prevailing policy rule, we focus on a serially uncorrelated shock.

The higher $\gamma$ does not have an effect on funds on impact because of the predetermination of financing decisions, but it represents a fall in internal funds at $t + 1$, which leads to an increase in firms’ leverage.
We will see below that under a Taylor rule this shock brings about a period of deflation, which would be quite persistent if the original shock were also persistent. The optimal policy response, instead, is to create a short-lived period of inflation. The impact increase in the price level lowers the real value of total funds, so as to decrease labor and production levels. Mark ups increase on impact, as output and consumption decrease, so that the future cut in internal funds can be partially offset. The higher profits allow firms to quickly start rebuilding their internal funds. The adjustment process is essentially complete after 3 years. When consumption starts growing towards the steady state, the real rate must increase. For given nominal interest rate, there must be a period of mild deflation.

The financial shock raises the distortion associated with the scarcity of internal funds. With the nominal interest rate at the zero bound, all monetary policy can do is to use price level policy to increase markups on impact and induce a faster accumulation of internal funds.
But the financial markup is still high and variable. The wedge between the marginal rate of substitution and the marginal rate of transformation will be equal to the financial markup in the deterministic equilibrium path after impact, 

$$\frac{u_c(t) A_t}{\alpha} = \frac{1}{1 - \mu_t G(\bar{w}_t) - f(\bar{w}_t) \frac{\mu_t \bar{w}_t \phi(\bar{w}_t)}{1 - \Phi(\bar{w}_t)}}.$$  \hspace{1cm} (42)

### 3.2 Optimal policy when a non-zero interest rate is optimal

In this section, we explore to which extent the optimal policy recommendations described above are affected by the fact that the nominal interest rate is kept constant at zero. In the calibration, we keep all other parameters unchanged, but we assume that there is a fixed share of government consumption $g > 0$. As discussed above, the optimal steady state level of the nominal interest rate increases proportionately. We therefore calibrate the government consumption share to generate a reasonably small steady state value of the nominal interest rate, namely $g = 0.02$.\(^{16}\)

#### 3.2.1 Technology shocks

In spite of the availability of the nominal interest rate as a policy instrument, the optimal response to a technology shock is the same as before. Policy replicates the response of the allocations which would be attained in a frictionless model, whether nominal interest rates can be moved or not. This result is striking, because it implies that, in reaction to technology shocks, the zero bound on nominal interest rates does not represent a constraint for monetary policy in our model.

The result, however, holds solely in reaction to technology shocks. As discussed next, the zero bound does represent a constraint for monetary policy in response to financial shocks.

Why is it optimal to keep nominal interest rates constant in response to technology shocks? The reason is that price level policy can adjust the real level of funds used in production and stabilize financial conditions. Given that financial markets are constant, if the nominal interest rate is constant, then the wedge between the marginal rates of substitution and transformation is stabilized. And that is what policy should do. Variable interest rates would add an additional distortion to an economy that is on average already distorted.

---

\(^{16}\)Compared to the $g = 0$ case, there is an increase in the steady state level of the credit spread, to 1.27%, and of the bankruptcy rate, to 6.7%.

26
This result that it is optimal to keep wedges constant is not general. It holds more generally, than just for the preferences and technology that we have assumed here. But there are conditions on preferences and technology under which it would not hold. The result is similar to the results on optimal mark ups in second best problems under sticky prices, as in Adão, Correia and Teles (2003). Adão et al. discuss conditions on preferences, technologies and shocks under which it is optimal to keep markups constant in a sticky price economy distorted by a monopolistic competition markup. There are also similarities between these results and the results on uniform taxation in the, second-best, optimal taxation literature. The conditions in that literature are conditions of separability in leisure and homotheticity that we have also assumed here.

3.2.2 Financial shocks

For all financial shocks, the flexibility of using the nominal interest rate allows policy to speed up the adjustment after financial shocks. The effect of these shocks on output is considerably mitigated. We illustrate this general result with a serially uncorrelated shock to $\gamma$.

The impulse responses to this shock under the optimal policy are shown in Figure 3, together with the impulse responses in the case where the Friedman rule is optimal. The most striking result is that the impact of this shock on output, which is persistently contractionary when the short term nominal rate is kept fixed at zero, is less contractionary and very short-lived when the interest rate can be reduced.

The reduction in policy rates improves credit conditions directly, because it also reduces loan rates – the increase in the credit spread is largely comparable to the case when the Friedman rule is optimal. After decreasing on impact, output can immediately return to the steady state, while consumption has to adjust at a lower pace because of the increase in aggregate monitoring costs. The mildly positive rate of growth of consumption along the adjustment path implies that the real interest rate must also be positive. Given the protracted fall in the policy interest rate, inflation must also fall persistently – and by slightly more than the nominal interest rate – after its impact increase.

Figure 3: Impulse responses to a fall in the value of internal assets under optimal policy
Note: Logarithmic deviations from the non-stochastic steady state. Uncorrelated shock. The lines with circles indicate impulse responses under optimal policy when \( g > 0 \); the solid lines report impulse responses under optimal policy already shown in Figure 2.

The impact effect of the shock on mark-ups is comparable to the case in which the Friedman rule is optimal, but the adjustment process is much faster.

To understand more clearly the difference between the two cases, it is useful to take into account conditions (27) and (38), that restrict the markups in each case. On impact the effects on all the variables are very similar. Note that the deposit rate is predetermined, and therefore cannot be adjusted on impact. There is only a difference in the level of the average mark up in the two cases. It is lower when the nominal interest rate is zero, but the response to shocks on impact is basically the same.

After impact, the nominal interest rate can be moved in one case, directly affecting the mark up while in the other case it is always equal to zero. The conditions are satisfied without
expectations, after the impact period

\[ \frac{u_c(t) A_t}{\alpha} = \frac{1}{1 - \mu_t G(\bar{\omega}_t) - f(\bar{\omega}_t) \frac{\mu_t \bar{\omega}_t \phi(\bar{\omega}_t)}{1 - \phi(\bar{\omega}_t)}}, \]

and

\[ \frac{u_c(t) A_t}{\alpha} = \frac{R_{t-1}}{1 - \mu_t G(\bar{\omega}_t) - f(\bar{\omega}_t) \frac{\mu_t \bar{\omega}_t \phi(\bar{\omega}_t)}{1 - \phi(\bar{\omega}_t)}}. \]

The effects on the financial variables - the bankruptcy rate, leverage, the spread, the real value of internal funds - are identical, so that the term \( 1 - \mu_t G(\bar{\omega}_t) - f(\bar{\omega}_t) \frac{\mu_t \bar{\omega}_t \phi(\bar{\omega}_t)}{1 - \phi(\bar{\omega}_t)} \) is the same in the two cases. The effects on output, consumption, and inflation are very different, because the reduction in the deposit rate, can offset the effects on the financial variables, and directly stabilize the mark ups \( \frac{u_c(t) A_t}{\alpha} \).

In the case where the nominal interest rate is always at the zero bound, completely stabilizing the mark up in response to a financial shock is clearly not feasible. The shock to internal funds is a shock to the death rate of entrepreneurs, that, because of the predetermination of assets produces effects one period after it is revealed. In the impact period there are already effects on the financial variables in order to increase mark ups, and profits, and speed up the process of accumulation of internal funds. In the case where the nominal interest rate can be adjusted, it still cannot be adjusted on impact. On impact, there are effects on the mark up. After the initial period movements in the policy rate could compensate for the financial markup given by \( \frac{1}{1 - \mu_t G(\bar{\omega}_t) - f(\bar{\omega}_t) \frac{\mu_t \bar{\omega}_t \phi(\bar{\omega}_t)}{1 - \phi(\bar{\omega}_t)}} \). The impulse responses show that optimal policy will not completely stabilize the mark up.

### 3.3 Taylor rule policy

We now compare the impulse responses under optimal policy and \( g > 0 \) with those in which policy follows the simple Taylor rule in equation (41).

#### 3.3.1 Technology shocks and the cyclicality of bankruptcies

In response to a negative technology shock, the simple Taylor rule tries to stabilize inflation (see Figure 4). The large amount of nominal funds that firms carry over from the previous period, therefore, has high real value. Given the available funds, firms hire more labor and the output contraction is relatively small, compared to what would be optimal at the new productivity level. As a result, the wage share increases and firms make lower profits, hence
they must sharply reduce their internal funds. Leverage goes up, and so do the credit spread and the bankruptcy rate. In the period after the shock, firms start accumulating funds again, but accumulation is slow and output keeps falling for a whole year after the shock. It is only in the second year after the shock that the recovery begins.

Figure 4 illustrates how our model is able to generate realistic, cyclical properties for the credit spread and the bankruptcy ratio. An increase in bankruptcies is almost a definition of recession in the general perception, while the fact that credit spreads are higher during NBER recession dates is documented, for example, in Levin, Natalucci and Zakrajsek (2004). Generating the correct cyclical relationship between credit spreads, bankruptcies and output is not straightforward in models with financial frictions. For example, spreads are unrealistically procyclical in the Carlstrom and Fuerst (1997, 2000) framework. The reason is that firms' financing decisions are state contingent in those papers. Firms can choose how much to borrow from the banks after observing aggregate shocks. Should a negative technology shock occur, they would immediately borrow less and try to cut production. This would avoid large drops in their profits and internal funds, so that their leverage would not increase. As a result, bankruptcy rates and credit spreads could remain constant or decrease during the recession.

In our model, economic outcomes are reversed because of the pre-determination in financial decisions. Firms' loans are no-longer state contingent, hence they cannot be changed after observing aggregate shocks. This assumption implies that firms are constrained in their impact response to disturbances. After a negative technology shock, firms find themselves with excessive funds and their profits fall because production levels do not fall enough. The reverse would happen during an expansionary shock, when production would initially increase too little and profits would be high.

Figure 4: Impulse responses to a negative technology shock under a Taylor rule
The model also generates a realistically hump-shaped impulse response of output and consumption without the need for additional assumptions, such as habit persistence in households' preferences. Once a shock creates the need for changes in internal funds, these changes can only take place slowly. Compared to the habit persistence assumption, our model implies that the hump-shape in impulse responses is policy-dependent. After a technology shock, optimal policy keeps internal funds at their optimal level at any point in time. Firms do not need to accumulate, or decumulate, internal funds, and, as a result, the hump in the response of output and consumption disappears.

A notable feature of Figure 4 is that the Taylor rule generates the "wrong" reaction of prices to the negative technology shock compared to optimal policy – a small deflation on impact, rather than inflation. The reason is related to the hump-shaped response of consumption, which implies that the real interest rate must fall for a few quarters after the shock. If inflation
increased on impact, the policy rate would have to increase by less than inflation in order to bring about a negative real interest rate. However, this policy response would be inconsistent with the rule in equation (41), which requires the interest rate to increase more than inflation. The fall in the real interest rate must therefore be implemented through a reduction in the nominal interest rate and a period of deflation.

This result is independent of the size of the inflation response coefficient in the Taylor rule – provided that the rule is consistent with a determinate equilibrium. If the inflation response coefficient were higher (lower), deflation would simply be smaller (larger). Only in the limiting case of a very large response coefficient would the outcome be not deflation, but a situation very close to price stability.

An implication of this result is that, after a technology shock, the higher the inflation response coefficient in the Taylor rule, the closer is the Taylor rule to optimal policy. Intuitively, price stability is closer to the inflationary outcome produced by optimal policy than the deflation rate generated by the Taylor rule. This property of the Taylor rule in our model is reminiscent of the results in Gilchrist and Leahy (2002) and Faia and Monacelli (2007), where a Taylor rule with a high inflation response coefficient delivers superior outcomes. The overall properties of the Taylor rule, however, are very different. Gilchrist and Leahy (2002) and Faia and Monacelli (2007) also assume sticky prices, and price stability is optimal in that environment. In our model, allocations under price stability would remain far away from the optimum. After a negative technology shock, the real level of funds would still be too high, so that production and consumption would come down in a hump-shape manner, rather than on impact as they should.

3.3.2 Shocks to the value of internal assets

A reduction in the value of internal assets leads to an increase in leverage, the economy’s bankruptcy rate and credit spreads (see Figure 5). As in the case of optimal policy (when \( g > 0 \)), the Taylor rule prescribes a fall in the policy interest rate. For similar reasons to those applying in the case of technology shocks, however, the Taylor rule brings about deflation, rather than inflation. Deflation keeps output too high on impact and generates a fall in mark-ups. As a result, the impact increase in leverage is more pronounced than under optimal policy. Consequently, the de-leveraging process is very slow and consumption is still away from the steady state three years after the shock. Compared to the optimal policy case, the recession
is more persistent and it comes at the cost of a higher bankruptcy rate and a higher credit spread.

Figure 5: Impulse responses to a fall in the value of internal assets under a Taylor rule

Note: Logarithmic deviations from the non-stochastic steady state. The shock is serially uncorrelated. The lines with crosses indicate impulse responses under the Taylor rule; the lines with circles report the impulse responses under optimal policy already shown in Figure 3.

Under a Taylor rule, this shock leads to a situation akin to the "initial state of over-indebtedness" described in Fisher (1933), in which firms' leverage increase and deflation ensues. In Fisher's theory, firms try to de-leverage through a fast debt liquidation and the selling tends to drive down prices. If monetary policy accommodates this trend, the price level also falls and the real value of firms liabilities increase further, leading to even higher leverage and further selling. In our model, over-indebtedness and leverage are also exacerbated by deflation, but the mechanics of the model are different. De-leveraging occurs through an accumulation of assets, rather than a liquidation of debt.
3.3.3 Policy shocks

Figure 6 shows the impulse responses to a serially correlated shock to the Taylor rule, corresponding to an increase in the policy rate.

The shock is useful to illustrate the general features of the monetary policy transmission mechanism in this model. These are characterized by the slow accumulation of internal funds, which produces very persistent responses in all variables.

Figure 6: Impulse responses to a monetary policy shock

Note: Logarithmic deviations from the non-stochastic steady state. Correlation of the shock: 0.9.

The shock generates an immediate increase in the price level which reduces the real value of firms’ nominal funds and induces a contraction in production and consumption through a fall in employment and real wages. Since leverage is predetermined in the first period, the lower production level brings about a reduction in the bankruptcy rate. Profits increase and, after one period, firms find themselves with an excess of internal funds. They therefore start
decumulating them, but the adjustment process is very slow. Three years after the shock, output, consumption and employment are still far away from the steady state.

4 The case in which internal and external funds are perfect substitutes

In order to better understand the results of the general model, we analyze a simplified case in which assets are predetermined, but internal and external funds are perfect substitutes - i.e. monitoring costs are zero.

Even in the absence of costly state verification, it is not optimal to stabilize inflation at all times. Hence, the predetermination of assets and the nominal denomination of funds are responsible for the deviation from price stability under the optimal policy in the general model.

We also use this model to evaluate the role played by asymmetric information and monitoring costs in explaining business cycle fluctuations. We find that, although these imperfections play a quantitatively minor role in determining the cyclical behavior of non-financial variables, they tend to amplify the reaction of the economy to shocks.

4.1 Inflation stabilization is not optimal

We consider the case where \( g > 0 \), and the nominal interest rate is high enough that the borrowing constraint of firms is always binding. In the model with financial frictions this was not necessary since positive financial markups guaranteed that the constraint was binding.

The equilibrium conditions in this economy are given by (3)-(6), together with

\[
R^d_{t-1} = R^d_{t-1} \equiv R_{t-1}, \quad t \geq 1 \tag{43}
\]

\[
E_{t-1} [v_t] = R_{t-1}, \quad t \geq 1
\]

\[
N_t = \frac{X_{t-1}}{W_t}, \quad t \geq 0 \tag{44}
\]

\[
v_t = \frac{A_t P_t}{W_t}, \quad t \geq 0 \tag{45}
\]

\[
c_t = (1 - g) A_t N_t, \quad t \geq 0. \tag{46}
\]

where \( R_t \) is the policy rate.
The implementability conditions restricting \( c_t, N_t, t \geq 0 \), and \( R_{t-1}, t \geq 1 \), are:

\[
E_{t-1} \left[ \frac{u_c(t) A_t}{\alpha} \right] = R_{t-1}, \quad t \geq 1
\]  
\( (47) \)

\[ c_t = (1 - g) A_t N_t, \quad t \geq 0 \]  
\( (48) \)

Every equilibrium sequence for \( c_t, N_t, t \geq 0 \), and \( R_{t-1}, t \geq 1 \), in this set can be implemented. The other equilibrium conditions are satisfied by the choice of the remaining variables: (43) determine \( R^l_{t-1} \) and \( R^d_{t-1}, t \geq 1 \). For \( t = 0 \), given a value \( X_{-1} \) and an allocation \( c_0 \) and \( N_0 \), (44) and (3) are satisfied by the choice of \( W_0 \) and \( P_0 \). For \( t \geq 1 \), given an allocation \( c_t \) and \( N_t \), and \( R_{t-1} \), conditions (3), (5) and (44) are satisfied by the choice of \( W_t \), \( P_t \) and \( X_{t-1} \). There are two contemporaneous conditions and one predetermined condition for two contemporaneous variables and one predetermined variable. (45) determines \( v_t \); (4) determines \( Q_{t-1,t}^{-1} \); and (6) restricts \( m_t \).

The restriction that government consumption is a constant share of production is a second-best restriction in this environment, implying the optimal use of proportionate taxation, even if lump-sum taxation is available. The optimal, second-best, allocation maximizes utility subject to the resource constraints

\[ c_t \leq (1 - g) A_t N_t. \]

Optimality requires that

\[ \frac{u_c(t)}{\alpha} = \frac{1}{(1 - g) A_t}, \quad t \geq 0. \]  
\( (49) \)

This optimal allocation can be implemented in this economy with predetermined assets, since it satisfies the implementability condition (47) when the interest rate is

\[ R_{t-1} = \frac{1}{1 - g}, \quad t \geq 1. \]

In this economy, monetary policy does much more than just setting the interest rate. Implementing the optimal allocation, requires moving the price level to adjust the real value of funds.

Under log-linear preferences, labor would not move in response to shocks to productivity, \( A_t \). Since funds are predetermined, in (44), the wage rate could not move either and, from (3), the price level would have to be inversely proportional to consumption, or to the shocks to productivity.
4.2 The role of asymmetric information and monitoring costs

Figure 7 compares the reaction to a technology shock under the Taylor rule in the general model of section 2 and in the model of this section. The figure shows that the differences between the two cases are not overwhelming, but the model with asymmetric information and monitoring costs tends to amplify business cycle fluctuations in response to shocks. Compared to the simpler model, the recession induced by a negative technology shock is deeper when accompanied by an increase in credit spreads and in the bankruptcy rate. Employment fluctuations are also more pronounced and so is the volatility of inflation and of the policy interest rate.
Figure 7: Impulse responses to a negative technology shock under a Taylor rule

Note: Logarithmic deviations from the non-stochastic steady state. Correlation of the shock: 0.9. The dashed lines report the impulse responses in the case where internal and external funds are perfect substitutes; the lines with crosses corresponds to those in Figure 4.

5 Conclusions

The model described in this paper represents an attempt to clarify the policy incentives created by the nominal denomination of firms’ debt. Our analysis is based on a number of simplifying assumptions and does not aim to provide quantitative policy prescriptions. Nevertheless, we highlight results that may be of relevance also in more general frameworks.

The first result is that maintaining price stability at all times is not optimal when firms financial positions are denominated in nominal terms and debt contracts are not state-contingent. After a negative technology shock, for example, an impact increase in the price level stabilizes firms’ leverage and allows for a more efficient economic response to the shock. This ability of
monetary policy to influence the real value of firms’ assets and liabilities derives from the assumption that, when shocks occur, financial contracts are predetermined. The policy response through the price level is such that, in response to technology shocks, there is no need for the central bank to adjust the nominal interest rate.

A second result is that the optimal response to an exogenous reduction in internal funds, which amounts to an increase in firms’ leverage, is to reduce the nominal interest rate, if the nominal rate is not at its zero bound, and to engineer a short period of controlled inflation. Both policy responses have the advantages of mitigating the adverse consequences of the shock on bankruptcy rates and of allowing firms to quickly de-leverage.

Finally, we show that a simple Taylor-type rule would produce significantly different economic outcomes from those prevailing if policy is set optimally. For example, under a Taylor rule bankruptcy rates would increase during recessions, as it appears to be the case in the empirical evidence. Bankruptcy rates would instead be acyclical under optimal policy.

A Appendix

A.1 The financial contract

Consider the optimal financial contract problem that maximizes (14) subject to (15) and (16), where \( f(\tilde{w}_{i,t}) \) and \( g(\tilde{w}_{i,t}; \mu_t) \) are given by (9) and (10), respectively, and \( \tilde{w}_{i,t} = \frac{R_{t-1}^i}{\tilde{W}_t} \left( 1 - \frac{Z_{t-1}^i}{X_{t-1}^i} \right) \).

The solution for \( \frac{Z_{t-1}^i}{X_{t-1}^i}, R_{t-1}^i, \) and \( \tilde{w}_{i,t} \) is the same across firms. Let \( z_{t-1} = \frac{Z_{t-1}^i}{X_{t-1}^i} \) and \( v_t \equiv \frac{P_{A_t} A_t}{W_t} \). We can define the function \( \tilde{w}_{i,t} \equiv \tilde{w}_t = \tilde{w} \left( R_{t-1}^i, z_{t-1}; v_t \right) \) as

\[
\tilde{w}_t = \frac{R_{t-1}^i (1 - z_{t-1})}{v_t}.
\]

We can rewrite the problem as

\[
\max E_{t-1} \left[ v_t \frac{1}{z_{t-1}} f \left( \tilde{w} \left( R_{t-1}^i, z_{t-1}; v_t \right) \right) \right]
\]

subject to

\[
E_{t-1} \left[ v_t g \left( \tilde{w} \left( R_{t-1}^i, z_{t-1}; v_t \right); \mu_t \right) \right] \geq R_{t-1}^d (1 - z_{t-1}) \quad (51)
\]

\[
E_{t-1} v_t f \left( \tilde{w} \left( R_{t-1}^i, z_{t-1}; v_t \right) \right) \geq R_{t-1}^d z_{t-1} \quad (52)
\]

where the functions \( f(\tilde{w}_{i,t}) \) and \( g(\tilde{w}_{i,t}; \mu_t) \) are given by (9) and (10), respectively.
Define as \( \lambda_{1,t-1} \) and \( \lambda_{2,t-1} \) the Lagrangean multipliers of (51) and (52) respectively. Conjecturing that \( \lambda_{2,t-1} = 0 \), the first-order conditions are

\[
0 = E_{t-1} \left[ -\frac{v_t}{z_{t-1}} f \left( \varpi \left( R^d_{t-1}, z_{t-1}; v_t \right) \right) + \frac{v_t}{z_{t-1}} f_2 \left( R^d_{t-1}, z_{t-1}; v_t \right) \right] + \lambda_{1,t-1} E_{t-1} \left[ v_t g_2 \left( R^d_{t-1}, z_{t-1}; v_t, \mu_t \right) + R^d_{t-1} \right]
\]

\[
E_{t-1} \left[ \frac{v_t}{z_{t-1}} f_1 \left( R^d_{t-1}, z_{t-1}; v_t \right) \right] + \lambda_{1,t-1} E_{t-1} \left[ g_1 \left( R^d_{t-1}, z_{t-1}; v_t, \mu_t \right) v_t \right] = 0
\]

where \( f_j \) and \( g_j \), with \( j = 1, 2 \), are the derivatives of \( f \) and \( g \) with respect to the first and second argument of the function \( \varpi \left( R^d_{t-1}, z_{t-1}; v_t \right) \).

We can rewrite these conditions as

\[
\lambda_{1,t-1} R^d_{t-1} z_{t-1} = E_{t-1} \left[ \frac{v_t}{z_{t-1}} f \left( \varpi \left( R^d_{t-1}, z_{t-1}; v_t \right) \right) \right],
\]

\[
R^d_{t-1} (1 - z_{t-1}) \lambda_{1,t-1} E_{t-1} \left[ \frac{\mu_t}{v_t} \phi \left( \frac{R^d_{t-1} (1 - z_{t-1})}{v_t} \right) \right] + \left( \frac{1}{z_{t-1}} - \lambda_{1,t-1} \right) E_{t-1} \left[ 1 - \Phi \left( \frac{R^d_{t-1} (1 - z_{t-1})}{v_t} \right) \right] = 0,
\]

\[
E_{t-1} \left[ g \left( \varpi \left( R^d_{t-1}, z_{t-1}; v_t \right); \mu_t \right) v_t \right] = R^d_{t-1} (1 - z_{t-1}).
\]

From the second condition, since \( z_{t-1} < 1 \) and \( \lambda_{1,t-1} > 0 \),

\[
R^d_{t-1} (1 - z_{t-1}) \lambda_{1,t-1} E_{t-1} \left[ \frac{\mu_t}{v_t} \phi \left( \frac{R^d_{t-1} (1 - z_{t-1})}{v_t} \right) \right] > 0.\]

Moreover, 1 > \( \Phi \left( \frac{R^d_{t-1} (1 - z_{t-1})}{v_t} \right) \) so that \( \lambda_{1,t-1} - \frac{1}{z_{t-1}} > 0 \) and \( \lambda_{1,t-1} z_{t-1} > 1 \). It follows that \( R^d_{t-1} z_{t-1} < E_{t-1} \left[ v_t f \left( \varpi \left( R^d_{t-1}, z_{t-1}; v_t \right) \right) \right], \) which verifies the conjecture that \( \lambda_{2,t-1} = 0 \).

Using the definition of the threshold, (50), the first-order conditions can be written as (18) and (19).

### A.2 Equilibria

The equilibrium conditions restricting the variables \( \{ c_t, N_t, v_t, P_t, R^d_t, \varpi_t, z_t, R^d_{t-1}, X_t, Z_t \} \) given \( z_{-1}, X_{-1}, Z_{-1} = z_{-1} X_{-1}, \) and \( R^d_{t-1} \), can be summarized by

\[
u_c(t) = \frac{v_t}{A_t}, \quad t \geq 0.
\]

(53)
\[
\frac{u_c(t-1)}{P_{t-1}} = R_{t-1}^d \beta E_{t-1} \frac{u_c(t)}{P_t}, \quad t \geq 1
\]  
(54)

\[
E_{t-1}[v_t f(\varpi_t)] = \frac{R_{t-1}^d}{1 - \frac{E_{t-1}[v_t f(\varpi_t)]}{E_{t-1}[1 - \Phi(\varpi_t)]}} z_{t-1}, \quad t \geq 1
\]  
(55)

\[
E_{t-1}[v_t g(\varpi_t; \mu_t)] = R_{t-1}^d (1 - z_{t-1}), \quad t \geq 1
\]  
(56)

\[
\varpi_t = \frac{R_{t-1}^d (1 - z_{t-1})}{v_t}, \quad t \geq 0
\]  
(57)

\[
N_t = \frac{v_t X_{t-1}}{A_t P_t}, \quad t \geq 0
\]  
(58)

\[
Z_{t-1} = z_{t-1} X_{t-1}, \quad t \geq 0
\]  
(59)

\[
Z_{t-1} = (1 - \gamma_{t-1}) f(\varpi_{t-1}) \frac{v_{t-1}}{z_{t-2}} Z_{t-2}, \quad t \geq 1
\]  
(60)

\[
(1 - g) A_t N_t [1 - \mu_t G(\varpi_t)] = c_t, \quad t \geq 0
\]  
(61)

The other equilibrium conditions determine the remaining variables.

Given the path for the price level there is a unique equilibrium for the other variables. To see this, notice that at \( t = 0 \), given the values of \( z_{-1}, X_{-1} \) and \( R_{t-1}^d \), the equilibrium for \( c_0, N_0, v_0, \varpi_0 \), can be determined using (53), (57), (58), and (61), for \( t = 0 \). Given these variables, \( Z_{-1} = z_{-1} X_{-1} \), and the path for the price level, \( P_t \), the remaining variables \( c_t, N_t, v_t, \varpi_t, Z_{t-1}, R_{t-1}^d, z_{t-1}, R_{t-1}^l, X_{t-1} \) for \( t \geq 1 \), are determined using (53)-(61), for \( t \geq 1 \). These are 4 contemporaneous variables and 5 predetermined variables, restricted by 4 contemporaneous conditions and 5 predetermined conditions. If \( P_t \) are set exogenously, all the other variables have a single solution. Alternatively, we could set exogenously \( R_{t-1}^d \), plus \( P_t \) in as many states as \( \#S^t - \#S^{t-1} \), and again there would be a unique equilibrium.

### A.3 Impulse responses to financial shocks

We present here additional impulse responses to financial shocks in the baseline model where the Friedman rule is optimal. Shocks are serially correlated with a 0.9 correlation coefficient.

In all cases, we compare the impulse responses under the optimal policy to those arising under the Taylor rule.
Figure A1: Impulse responses to an increase in $\sigma_{\omega t}$

Note: Logarithmic deviations from the non-stochastic steady state. Correlation of the shock: 0.9. The lines with crosses indicate impulse responses under the Taylor rule; the lines with circles report the impulse responses under optimal policy (in the $g > 0$ case).

Figure A1 shows the impulse responses to a persistent increase in the riskiness of the economy, i.e. to an increase in the standard deviation of the idiosyncratic shocks $\sigma_{\omega t}$. This shock is associated with a prospective worsening of credit conditions and an increase in the bankruptcy rate.

As in the case of the negative shock to the value of internal assets (the $\gamma_t$ shock), optimal monetary policy (the line with circles) engineers on impact an increase in the price level to reduce output. The financing conditions stipulated before the shock are ex-post favorable to firms: on impact, the output contraction enables them to make higher profits, so that they will accumulate more internal funds in the following period. This increase in internal funds allows for a fast economic recovery, because a contemporaneous fall in the policy rate neutralizes the effects of the increase in credit spreads.
The impulse responses to this shock are qualitatively similar to those to a shock in the value of firms’ internal assets. The main exception is the response of leverage, which falls after a $\sigma_{\omega_{t-1}}$ shock and increases after a $\gamma_t$ shock. The reduction of leverage observed in Figure A1 under optimal policy is a direct result of the impact increase in firms’ profits. This is consistent with the temporary increase in the volatility of idiosyncratic shocks at almost unchanged (except on impact) consumption and hours worked. Even if the shock is serially correlated, output and consumption are back at the steady state after one quarter.

Figure A2: Impulse responses to an increase in $\mu_t$

Note: Logarithmic deviations from the non-stochastic steady state. Correlation of the shock: 0.9. The lines with crosses indicate impulse responses under the Taylor rule; the lines with circles report the impulse responses under optimal policy (in the $g > 0$ case).

Under the Taylor rule (the line with crosses), there is also a sharp decrease in the deposit rate but, contrary to the optimal policy case, the price level falls on impact. This prevents the initial contraction of output and consumption. As a result, leverage, bankruptcy rates, and
spreads are higher than under the optimal policy. Internal funds are accumulated at a slower pace and the recession is longer lasting.

Figure A2 plots the responses to an exogenous increase in the proportion of total funds lost in monitoring activities, \( \mu_t \). This is different from the shock previously analyzed because it mechanically implies a higher waste of resources per unit of output. The optimal policy response is to reduce output in order to minimize the resource loss. If the shock was not serially correlated, this would once again be achieved through an impact increase in the price level. Since the shock is persistent, however, policy needs to manage a trade-off between immediate and future resource losses. An impact increase in the price level would not only immediately reduce output, but it would also lead to more profits and a faster accumulation of internal funds, hence large future losses in monitoring activity as long as \( \mu_t \) remains high. Compared to this scenario, future losses would be minimized if the price level were instead cut on impact, so as to slow down the accumulation of internal funds.

The trade-off between minimizing current and future losses leads to an impact fall in the price level under optimal policy. This increases the real value of firms’ funds and, in turn, allows firms to expand production. The ensuing increases in credit spreads and in bankruptcy rates are countered by a contemporaneous fall in the policy rate. As in the case of the other financial shocks, optimal policy ensures a fast adjustment process: after one quarter, output and hours are back in steady state, and fluctuations in consumption and mark-ups become negligible.

In reaction to a shock to \( \mu_t \), the price level and the policy interest rate fall less under the Taylor rule. As in the case of other financial shocks, this reaction leads to a more protracted contraction in both output and consumption.
